AB The magnetic properties of randomly oriented assembly of
noninteracting single-domain particles with cubic anisotropy are studied
in detail. Both signs of the cubic anisotropy constant are considered. We
analyze the irreversible jumps of particle magnetization by
means of direct solution of the Landau-Lifshitz-Gilbert (LLG) equation in
case when several equilibrium positions are available for a disappearing
magnetization state. It is shown that a particular
hysteresis loop of a particle with cubic anisotropy may
depend on the value of the damping parameter in the LLG equation. On the
other hand, the upper and lower bounds for the coercive force
of an assembly stated in the paper turn out to be very close to each

other. The physical reason for the closeness of the upper and lower bounds is the fact that, for particles with cubic type of magnetic anisotropy, the fraction of the uniquely determined particular hysteresis loops is rather large. As a result, the coercive force of randomly oriented assembly with cubic anisotropy is almost independent of the value of the damping parameter. It is also shown that it has only weak dependence on the value of the second cubic anisotropy constant.

AB Magnetic Langmuir-Blodgett multilayers of two ferritin molecules 1 and 2, containing, respectively, 4220 and 3062 Fe atoms have been prepared by using the adsorption properties of a 6/1 mixed monolayer of dioctadecyldimethylammonium bromide (DODABr) and methyl stearate (SME). Transfer ratios close to unity were reached giving rise to LB films with a strong red colour. Infrared and UV-vis spectroscopy indicates that ferritin molecules are incorporated within the LB films. Magnetic measurements show that the superparamagnetic properties of these molecules are preserved. Thus, a marked hysteresis loop of magnetisation is obtained for LB films of 1 and 2 with a coercive field of 3400 and 2400 G, respectively.

AB A novel method was developed to prepare functionalized magnetic beads, in which superparamagnetic Fe₃O₄ core was synthesized with an injection-precipitation method and then was coated with functional groups using one-step suspension polymerization. In the coating and functionalizing process, a unique coupling reagent, bis-(2-hydroxyethyl methacrylate) phosphate, was introduced so that the monomers polymerized only on the surface of the nanocrystals without forming separate nuclei. The thickness of the coating layer and the size and density of the coated nanobeads were controlled by changing the quantity of the coated monomers. The nanobeads were characterized by transmission electron microscopy, light scattering spectrometry, Fourier transformation infrared spectroscopy. X-ray fluorescence spectroscopy and the magnetic hysteresis loop determination method. The carboxyl-modified magnetic nanobeads were employed to simplify the isolation of genomic DNA from human whole blood.

AB We have grown precisely ordered and precisely located arrays of ultra-small magnetic dots. The nanofabrication process is based on the use of a protein crystal etch mask which is used to create a hexagonal lattice of holes in Si substrates. An assembly of (Fe/Pd).sub.4 dots with the average dot size of 10 nm in diameter, 6.5 nm height, and an average separation between dot centers of 22 nm was grown using molecular-beam epitaxy. The dot locations are determined by the biological mask that is used to create ordered arrays of .eqvsim.4 nm deep holes in Si. Fe/Pd multilayers (1 nm thick Fe and 0.4 nm thick Pd layers) were deposited to create dots within these holes. The dots extend .eqvsim.2.5 nm above the surface, with a thicker (1.5 nm) final layer of Pd for protection of these structures during measurements. Magneto-optical Kerr effect and magnetometry data showed that these objects are magnetic even at room temperature and are fairly soft with a coercive field of .eqvsim.40 Oe. Measurements of the hysteresis loop revealed that magnetization is in plane and that $4\pi M_{\text{eff}}$ is on the order of 15 kG. .COPYRGT. 2003 American Institute of Physics.

AB Magnetic viscosity measurements were made on native horse-spleen ferritin in zero applied magnetic field at temperatures between 2 and 21 K. The data have been used to calculate the apparent magnetic-moment-weighted energy barrier distribution for the sample of ferritin. The distribution is composed of a log-normal distribution plus a second distribution that is well described by an exponential decay of barrier frequency with increasing barrier height. The two distributions contribute approximately equally to the overall distribution. The log-normal distribution has its peak at an energy barrier of approximately 3×10^{-21} J, while the decay constant for the second distribution has a value of approximately 2×10^{-21} J. The existence of the low-energy barrier distribution with exponentially decaying shape in conjunction with the observation of shifted field-cooled magnetic hysteresis loops is interpreted as strong evidence for the existence of multiple interacting magnetic entities within each ferritin particle.

AB A novel method was developed to prepare functionalized magnetic beads, in which superparamagnetic Fe₃O₄ core was synthesized with an injection-precipitation method and then was coated with functional groups using one-step suspension polymerization. In the coating and functionalizing process, a unique coupling reagent, bis-(2-hydroxyethyl methacrylate) phosphate, was introduced so that the monomers polymerized only on the surface of the nanocrystals without forming separate nuclei. The thickness of the coating layer and the size and density of the coated nanobeads were controlled by changing the quantity of the coated monomers. The nanobeads were characterized by transmission electron microscopy, light scattering spectrometry, Fourier transformation infrared spectroscopy. X-ray fluorescence spectroscopy and the magnetic hysteresis loop determination method. The carboxyl-modified magnetic nanobeads were employed to simplify the isolation of genomic DNA from human whole blood.

AB We have grown precisely ordered and precisely located arrays of ultra-small magnetic dots. The nanofabrication process is based on the use of a protein crystal etch mask which is used to create a hexagonal lattice of holes in Si substrates. An assembly of (Fe/Pd).sub.4 dots with the average dot size of 10 nm in diameter, 6.5 nm height, and an average separation between dot centers of 22 nm was grown using molecular-beam epitaxy. The dot locations are determined by the biological mask that is used to create ordered arrays of .eqvsim.4 nm deep holes in Si. Fe/Pd multilayers (1 nm thick Fe and 0.4 nm thick Pd layers) were deposited to create dots within these holes. The dots extend .eqvsim.2.5 nm above the surface, with a thicker (1.5 nm) final layer of Pd for protection of these structures during measurements. Magneto-optical Kerr effect and magnetometry data showed that these objects are magnetic even at room temperature and are fairly soft with a coercive field of .eqvsim.40 Oe. Measurements of the hysteresis loop revealed that magnetization is in plane and that $4\pi M_{\text{eff}}$ is on the order of 15 kG. .COPYRGT. 2003 American Institute of Physics.

AB Magnetic viscosity measurements were made on native horse-spleen ferritin in zero applied magnetic field at temperatures between 2 and 21 K. The data have been used to calculate the apparent magnetic-moment-weighted energy barrier distribution for the sample of ferritin. The distribution is composed of a log-normal distribution plus a second distribution that is well described by an exponential decay of barrier frequency with increasing barrier height. The two distributions contribute approximately equally to the overall distribution. The log-normal distribution has its peak at an energy barrier of approximately 3×10^{-21} J, while the decay constant for the second distribution has a value of approximately 2×10^{-21} J. The existence of the low-energy barrier distribution with exponentially decaying shape in conjunction with the observation of shifted field-cooled magnetic hysteresis loops is interpreted as strong evidence for the existence of multiple interacting magnetic entities within each ferritin particle.

AB An electronic control system for the measurement of hysteresis curves of microscopically observed magnetic structures such as chains of magnetosomes in magnetotactic bacteria suspended or swimming in water is

described. Using continuous magnetic fields generated by four coils for guidance or orientation of the bacteria or other magnetic structures, and pulsed magnetic fields in two additional coils for changing the degree of magnetization in small steps, hysteresis curves can be traversed. The circuits described can be constructed with readily available components. The guiding- and pulsed-field coils can be fashioned in any standard machine shop. The typical sensitivity of the system is better than 10^{-12} ergs/G, which makes a wide range of bacteria accessible to quantitative measurement of their magnetosome chains. The electronic circuits as well as the coil systems are described in detail. .COPYRGT. 2001 American Institute of Physics.
